TITLE: Unusual presentation of a retinoblastoma (A rare case)

ABSTRACT

Introduction:
Although a retinoblastoma is a well recognized condition it is still associated with a high mortality rate especially in developing countries because partly patients tend to present at very late stages to the health facilities. The mean age of occurrence of a retinoblastoma is 18 months and the age range of a retinoblastoma occurrence is 0-5 years. Diagnosing a retinoblastoma above the age of 6 years is extremely rare and exceptional.

Case Report:
We present a rare case of an 8 years old female patient presented with a 6 months history of a fast growing right eye mass and proptosis. The mass was fungating and septic.

The patient had normal developmental milestones. At presentation the body weight=21.40kg. The vital signs were within normal limits (Temperature=36.8 degrees Celsius, Pulse=83 b/min. Blood pressure=116/77 mmHg).

The diagnosis of a retinoblastoma was highly suspected on clinical and Radiological imaging but due to patient’s age there was also a suspicion of a rhabdomyosarcoma of the orbit.

Biopsy was performed and the diagnosis of a retinoblastoma was confirmed and the patient was then started on chemotherapy. The patient later demised while on treatment due to a disease progression.

Conclusion:
A retinoblastoma shows some typical imaging findings on Computed Tomography and on Magnetic Resonance Imaging and a multi-disciplinary approach helps greatly to secure the diagnosis and that helps improve the patient’s management and prognosis.

TITLE: Unusual presentation of a retinoblastoma (A rare case)

INTRODUCTION
Retinoblastoma is a rare malignant intra-ocular tumour that arises in the retinal neuro-ectodermal cells of infants and children and the angiogenic potential of the tumour correlates well with its aggressive nature [1, 2].
Retinoblastoma is estimated to represent 3% of all childhood cancers and is a blinding, devastating and a life threatening disease in the paediatric population [3, 4].
The estimated incidence of the retinoblastoma ranges from 1 in 15000 to 1 in 20000 live births and the mean age at diagnosis is 18 months [7, 8]. This case is presented because it falls within the extremely rare spectrum of retinoblastoma presentation which is known to present commonly up to 5 years of age in the literature.

CASE REPORT
An 8 years old female patient presented with a 6 months history of a fast growing right eye mass and proptosis. The mass was fungating and septic. The parents reported that there is no known past medical history of the patient.
The birth history shows that the patient was born through a normal vaginal delivery with an uneventful birth history. The birth weight was 3.1 kg and 48 cm in length. The Apgar score was 10/10. The patient had normal developmental milestones. At presentation the body weight=21.40kg. The vital signs were within normal limits (Temperature=36.8 degrees Celsius, Pulse=83 b/min. Blood pressure=116/77 mmHg).
The full blood count results were as follows:
White cell count was low =3.50 x 10^9 /L, Low red cell count=3.27x10^9 /L, Low Haemoglobin =9.0L g/dl, Low Haematocrit=0.267 L/L, The platelet count was high=589x10^9 /L.
Urea and creatinine results were within normal limits. The liver function tests, ESR and the CRP results were also within normal ranges e except for the lactate dehydrogenase that was markedly elevated at 1216 U/L while the maximal normal reference range is 295U/L.
Computed tomography was booked urgently and it showed an aggressive right orbital soft tissue mass that had ruptured the right globe with extension of the mass to the surrounding soft tissue and the area of the right optic nerve with no intracranial extension.

Significantly the anterior aspect of the mass demonstrated a large calcification. Biopsy was performed and the biopsy results confirmed a Retinoblastoma.

The histopathology report in our case was as follows:

Microscopic examination: Sections demonstrate conjunctival tissue within which there is an underlying infiltrating malignant small round blue cell tumour. The tumour is arranged as sheets of cells with a rim of basophilic cytoplasm, vesicular nuclei and occasional prominence of nucleoli. There is brisk mitotic activity and apoptosis. The lesion demonstrates numerous vestibule Flexner-Wintersteiner rosettes.

The tumour extends into the overlying stratified squamous epithelium and there is associated ulceration and mixed inflammation and the above mentioned features are those of a retinoblastoma.

The patient was then started on chemotherapy and the chemotherapy medication that was given was a 1.2 mg of Vincristine intravenously and Stat, 120 Mg of Etoposite in 200 ml of normal saline over 2 hours for 2 days and Carboplatine 240 mg in 200 ml 5% over 2 hours for 2 days.

Initially the patient appeared to have tolerated chemotherapy very well but due to disease progression the child died later while she was in the continuous course of chemotherapy.

DISCUSSION

A retinoblastoma is a rare malignant intra-ocular tumour that arises in the retinal neuro-ectodermal cells of infants and children and the angiogenic potential of the tumour correlates well with its aggressive nature [1, 2].

Retinoblastoma is estimated to represent 3% of all childhood cancers and is a blinding, devastating and a life threatening disease in the paediatric population [3, 4].

Retinoblastoma is the eye carcinoma that develops rapidly and can either be heritable or inheritable [5]. A heritable retinoblastoma typically presents in younger patients commonly younger than the age of one year whereas the inheritable type
presents in patients who are older than the age of one year [13, 14]. The incidence
of subsequent neoplasms is markedly increased in patients with a heritable form of
retinoblastoma and melanoma is the commonest of the subsequent neoplasms in
long term retinoblastoma survivors [15].
Familial history of retinoblastoma is noted in 10% of patients and in familial
retinoblastoma the germ-line is transmitted from generation to generation and the
pathology results from that the mutation has occurred in some ancestor [2, 6].
The estimated incidence of the retinoblastoma ranges from 1 in 15000 to 1 in 20000
live births and the mean age at diagnosis is 18 months [7, 8].
The unilateral cases of retinoblastoma are commonly diagnosed at 24 months of age
while the bilateral cases are diagnosed before the age of 12 months [8].
Children are diagnosed with retinoblastoma between the ages of 0-5 years of age
and it is known that 80% of retinoblastoma cases are diagnosed prior the age of
three years while 95% of retinoblastoma cases are diagnosed before the age of 5
years and reports are scanty regarding a retinoblastoma occurring after the age of
six [10]
The latter statement makes the case we are presenting extremely rare and
exceptional because in our patient a diagnosis of a retinoblastoma was made for the
very first time at the age of 8 years.
Retinoblastoma presents with calcifications in 90% of cases which sets this tumour
apart from the rest of the eye pathologies which entail but not limited to Toxocariasis,
Coat’s disease, Persistent hyperplasic primary vitreous and Retro-lental fibroplasia
[2].
An Ophthalmologist performs both fundoscopy and ultrasound to diagnose a
retinoblastoma and in almost all cases of retinoblastoma an intra-tumoral
calcification is evident on ultrasound which a high confidence level pertaining to the
diagnosis [12].
Evaluation of a retinoblastoma for a laterality, tumour size and localization, number
and tumour seeding can be confidently achieved with Fundoscopy and ultrasound
[12].
It is of utmost importance noting that the management of a patient with a
retinoblastoma needs a multi-disciplinary co-operation which involves radiologists,
paediatric oncologists, radiation oncologists, ophthalmologists and many other related specialities [9].

The danger of not treating a retinoblastoma is that the tumour grows and produces seeding in the eye complicated by retinal detachment, necrosis and invasion of the optic nerve, orbit and the central nervous system [11].

The primary role of a Radiologist in the management of a child with a retinoblastoma is to determine the spread of the tumour (optic nerve infiltration, skeletal breakthrough and to determine if there is metastasis to the liver, lymph nodes and to the meninges [2].

In most instances depending on the availability of resources most Radiologists avoid performing Computed tomography (CT) in patients with retinoblastoma due to long term increased risk for malignancy and that makes the Magnetic Resonance Resonance (MRI) the better tool for diagnosing and for the staging of a retinoblastoma [10].

Some of the MRI findings of a retinoblastoma involve [10]:

- T1 weighted image: Higher signal intensity compared to the normal ocular fluid
- T2 weighted image: Hypo-intense lesion compared to the ocular fluid
- Diffusion Weighted Image (DWI): Reduced diffusion
- T1 weighted image with contrast: Enhancing tumour presumable secondary to high cellularity of the tumour.

**CONCLUSION**

The diagnosis of a retinoblastoma involves a multi-disciplinary approach and imaging modalities include fundoscopy complimented by ultrasound, Computed Tomography and Magnetic Resonance Imaging. Retinoblastoma is commonly diagnosed before the age of five and it is extremely rare after the age of six. Education of the community to seek early medical help may reduce the mortality associated with a retinoblastoma in the developing countries.
