TITLE: Acute Pacing-Induced Cardiomyopathy

ABSTRACT

Introduction
PICM is defined as a 10% reduction in the left ventricular ejection fraction (EF) over several months to a year after pacemaker implantation, resulting in an EF of less than 50%. Nonetheless, other causes of cardiomyopathy should be excluded to diagnose patients with this condition.

Case Report
A 59-year man who presented with a third-degree heart block and underwent pacemaker implantation with right ventricular pacing. Subsequently, he manifested with an acute heart failure exacerbation and a reduced ejection fraction within two months of pacemaker implantation. Consequently, he underwent further workup to exclude causes of dilated cardiomyopathy such as acute coronary syndrome, sarcoidosis, hemochromatosis, granulomatosis with polyangiitis, and eosinophilic myocarditis. His left heart catheterization showed worsening in his ejection fraction without any significant coronary stenosis. He had an endomyocardial biopsy, which showed fibroblast proliferation and fibrosis with no evidence of any infiltrative cardiomyopathy. Because other causes of cardiomyopathy were ruled out, this patient was diagnosed with Pacing-induced cardiomyopathy. Thus, his cardiac pacemaker device was upgraded to Biventricular pacing device with Implantable Cardioverter Defibrillator.

Conclusion
Our report describes a patient with a severe acute form of Pacing-Induced cardiomyopathy and discusses the prevention and therapy of this condition.

Keywords: Cardiomyopathy, Pacing, Pacemaker
INTRODUCTION

The first pacemaker devices became available in the late 1960s and have since become the mainstay of therapy for patients with complete heart block [1]. Since that time, pacemaker implantation has risen dramatically because of both the increase in clinical indications for pacemaker use and the aging of the population. This increased use has lowered the mortality rate and improved quality of life among patients with cardiac arrhythmia [2]. Nevertheless, artificial pacing has been associated with detrimental effects on left ventricular function in patients who require right ventricular pacing such as patients with complete heart block [3]. Several animal studies have shown that right ventricular pacing reduces tissue perfusion and increases norepinephrine release in myocardial muscles [4]. Furthermore, it results in histological changes that include myofibrillar cellular disarray and dystrophic calcifications [5]. After heart block was induced by ablation and pacemakers were subsequently implanted, such histological changes in animals’ hearts develop within 3–4 months. This adverse clinical phenomenon is called pacing-induced cardiomyopathy (PICM).

PICM is defined as a 10% reduction in the left ventricular ejection fraction (EF) over several months to a year after pacemaker implantation, resulting in an EF of less than 50% [6]. Nonetheless, other causes of cardiomyopathy should be excluded to diagnose patients with this condition [6]. PICM has been reported in up to 9% of patients who have right ventricular pacing and 1% who have biventricular pacing [7]. Patients with this condition usually present with symptoms of congestive systolic heart failure such as exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, and lower extremity edema. A recent study revealed several factors that raise the risk of PICM such as male gender, a low EF, and a wide QRS [6]. Our report describes a patient with a severe acute form of PICM and discusses the prevention and therapy of this condition.
CASE REPORT

A 59-year Filipino man with a past medical history of hypertension, hyperlipidemia, and asthma, who started having syncopal episodes associated with coughing four years before admission, which was thought to be vasovagal syncope. At the time, no cardiac rhythm abnormalities were appreciated in his EKG, and he was started on new bronchodilators for a presumed asthma. Currently, he started having syncopal episodes again with concern for seizures. He was evaluated by Neurology and found to have a normal electroencephalogram (EEG) and no gross intracranial abnormalities on computed tomography (CT) of the head without contrast. Therefore, he was referred to cardiology clinic to evaluate his syncope and was found to have new complete heart block with a ventricular escape. He has a remote history of travel to the Philippines, no history of transfusions, recent international travel, no new industrial exposures, medication changes, sick contacts or insect bites. He has significant alcohol use, 4-5 drinks daily for over 40 years. Labs revealed persistent eosinophilia for six years. Immunologic workup was negative for JAK2, PDGFRα, PDGFRβ, FGFR1, p-ANCA, c-ANCA but showed elevated serum IgE levels. He was also negative for Trypanosoma cruzi and Schistosoma antibodies. Transthoracic echocardiogram (TTE) showed an EF of 45%, right ventricular systolic pressure (RSVP) 38mmHg, global hypokinesis of the left ventricle and right atrial (RA) pressure of 3 mmHg. Cardiac MRI revealed mildly dilated left ventricle, EF 45% and diffuse subendocardial enhancement on late gadolinium imaging with some areas of transmural involvement, thought to be due to fibrosis or inflammation (Figure 1). A dual chamber Biotronik DDD pacemaker was placed, and he continued follow-up with cardiology clinic with his device functioning appropriately.

He subsequently presented two months after pacemaker placement with worsening shortness of breath with exertion over a period of few weeks along with palpitations and anxiety. His repeat echocardiogram showed a severely dilated left ventricle and left atrium, moderately dilated right ventricle, severely reduced left ventricular systolic function with an EF 20-25%, moderately reduced right ventricular systolic function, septal and apical akinesia with RVSP 30-40 mmHg and RA pressure 15 mm Hg. Following aggressive diuresis to euvoolemia, he was discharged with furosemide, high dose atorvastatin, metoprolol to follow-up with heart failure clinic for continued
management and workup. He then underwent an elective left heart catheterization as an outpatient, which showed EF of 15%, end diastolic pressure 30mmHg, luminal irregularities in the left anterior descending artery but coronaries otherwise non-obstructive coronary artery disease with right dominant circulation. Right heart catheterization revealed Fick cardiac output of 2.7L/min and Fick cardiac index of 1.5L/min/m2, pulmonary capillary wedge pressure (PCWP) 30mmHg, mean pulmonary artery (PA) pressure 33mmHg. Endomyocardial biopsy was obtained and revealed fibroblast proliferation and fibrosis but otherwise unremarkable myocardial cells (Figure 2). Congo red staining was negative for amyloid disease. Because other causes of cardiomyopathy were ruled out, this patient was diagnosed with PICM. Biventricular pacemaker upgrade was performed after that because his heart function did not improve with optimal medical therapy. His EKG shows narrow QRS waves after he had this procedure (Figure 3), and his CXR confirms that his cardiac device leads were in a proper position.

DISCUSSION
Right ventricular pacing altered the function and the geometry of the left ventricle function. This resulted primarily from the left ventricular dyssynchrony induced by functional left bundle branch block, especially among patients with predominant pacing [8, 9, 10]. As demonstrated in animal studies, right ventricular pacing reduces tissue perfusion and increases norepinephrine release, which leads to myofibrillar cellular disarray and dystrophic calcifications [4,5]. Therefore, those patients also have a higher incidence of atrial fibrillation, ventricular arrhythmia, heart failure hospitalization, and death [8,11]. Nevertheless, this disease does not occur in all patients with right ventricular pacing despite the fact that left ventricular dyssynchrony is very common among those patients [12]. It is unclear whether patients with pacing–induced cardiomyopathy (PICM) have certain factors that increase their risk for this disease.
To the best of our knowledge, this is the first case report discussing an acute and severe form of PICM. In this case, it was unclear why this patient manifested with a serious and intense form of this disease or whether biventricular pacing could have prevented this disease in this patient. Several studies have shown that, in
comparison with right ventricular pacing, biventricular pacing preserves and improves left ventricular function in patients with normal (>40%) and low (<40%) EFs [13, 14]. Yu et al. found no significant differences in the rates of hospitalization or death between right ventricular pacing and biventricular pacing in patients that have a normal EF (45%) and an indication for pacing [7]. However, Curtis et al found significant difference in the rate of hospitalization but no difference in the rate of death in patients who have indications for pacing with atrioventricular block, class I, II, or III heart failure, and EF less than 50% [15]. We think, that this patient had a serious and intense form of this disease because he had subendocardial inflammation and fibrosis before pacemaker placement, which might increase his risk to develop PICM. He also had risk factors for PICM including being male and having a low EF and wide QRS. The rule of cardiac MRI in predicting PICM among patients with normal EF (45%) and atrioventricular block remains unclear to determine whether certain groups of patients might benefit from biventricular pacing instead of a right ventricular pacemaker.

Patients with PICM are usually treated effectively with medical therapy as well as cardiac resynchronization therapy (CRT). Schwerg et al. showed in a recent clinical study that CRT significantly improves the function of left ventricular function among patients with PICM who received an optimal medical therapy. In this study, patients who declined a CRT upgrade did not show any significant improvement in their left ventricular function within one year of optimal medical therapy [16]. Our patient's device was upgraded to CRT because he did not improve with an optimal medical therapy. An echocardiogram will be repeated within three months to evaluate the effect of CRT on his LV function.

CONCLUSION
Pacing-induced cardiomyopathy is defined as a 10% reduction in the left ventricular ejection fraction over one year after pacemaker implantation, resulting in an EF of less than 50%. Biventricular pacing preserves and improves the left ventricular function in patients with normal (>40%) and low (<40%) ejection fractions. Further studies are warranted to confirm the prognostic effect of cardiac MRI in predicting pacing-induced cardiomyopathy in patients who have a normal ejection fraction
(45%) and an indication for pacing such as patients with atrioventricular block. Such groups of patients might benefit from biventricular pacing instead of a right ventricular pacemaker.

**CONFLICT OF INTEREST**

None of the authors report any conflicts of interest related to this article.

**AUTHOR’S CONTRIBUTIONS**

Talal Alzahrani, Sripooja Satya, and Marco Mercader had full access to all of the data of the case report and take responsibility for the integrity of the data. All authors contributed to the case report concept and manuscript. Sripooja Satya acquired the data, and Talal Alzahrani drafted the manuscript. All authors contributed to interpretation of the patient’s data and to the critical revision of the manuscript for important intellectual content.
